Abstract: The objective of this paper is to design a heart rate (HR) controller for a treadmill so that the HR of an individual running on it tracks a pre-specified, potentially time-varying profile specified by doctors for the cardiac recovery of the person. Initially, a parameter estimation algorithm is presented with the aim of estimating the values of the parameters of a model relating the speed of the treadmill with the HR of an individual. The parameter estimation problem is formulated as an optimization one and solved by using Particle Swarm Optimization (PSO). Afterwards, a super-twisting sliding mode controller is designed to perform the robust control of treadmill’s speed in the presence of potential unmodelled dynamics or parametric uncertainties. Numerical examples show that the estimation procedure is able to obtain accurate values for the system’s parameters while the proposed control approach is able to obtain zero tracking error without chattering, definitely achieving the control objectives. In both cases the range of treadmill’s speed goes from 2 to 14 km/h, range that is not usually employed in previous studies.

Keywords: Heart rate control, PSO Identification of nonlinear systems, Super-twisting sliding mode control

1. INTRODUCTION

The objective of this paper is to design a heart rate (HR) controller for a treadmill so that the HR of an individual running on it tracks a pre-specified, potentially time-varying profile specified by doctors for the cardiac recovery of the person. The controller modifies the speed of the treadmill so as to make individual’s HR track such a profile. The ability to control the Heart Rate (HR) in treadmill exercise is of the great importance in design of exercise routines and it is one of the most significant vital signs to reflect cardiovascular events, (Hunt et al, 2016). The understanding of HR response with exercise may lead also to an improvement in developing training protocols for athletics, more efficient weight loss protocols for the overweight people, and in facilitating assessment of physical fitness and health of individuals, (Anselmio et al, 2017), (Armagh et al, 2017), (Weippert et al, 2014). In addition, treadmill exercise has an important role for people recovering from cardiac disease or surgery as well as for people involved in weight loss programs, (Dan and Dragumir, 2012). The design of the controller follows two steps. The first one is the modeling of the HR response to the treadmill exercise while the second one designs the controller based on the previous model by means of a sliding mode control.

Several models have been proposed in the literature to model heart rate response to treadmill velocity, (Jang and Dae-Geun, 2016), (Cheng et al, 2008), (Peter and Huber, 1964). For instance, (Shtessel and Yuri, 2010) proposes a Hammerstein model composed of a static non-linearity defined by a look-up table followed by a linear dynamical system, while (Zhang et al, 2011) and (Scalzi et al, 2012) propose a nonlinear dynamical model. Anyway, nonlinearity must be present in the model due to the nonlinear response of the heart rate to the exercise. In this study, we use the nonlinear dynamical system proposed by, (Zhang et al, 2011), (Wang et al, 2007), (Rini et al, 2014), which is able to capture the dynamic behavior in a compact way by means of a reduced number of parameters, fact that is convenient for control purposes.

Heart rate treadmill models are parametrized by a number of parameters that capture the individual HR response to exercise, (Kranjec et al, 2014), (Mayer et al, 2018). It is vital, thus, to design parameter estimation procedures that allow us to have a personalized model for each individual from measured data. In this work, parameter estimation is set up as an optimization problem whose solution leads to the estimated model parameters. The optimization problem is solved by using a Particle Swarm Optimization (PSO) algorithm.

Particle swarm optimization was introduced by Kennedy and Eberhart in 1995, (Yan et al, 2013), (Shtessel and Yuri, 2010). At that time, the wide success of Evolutionary Algorithms (EAs) motivated researchers worldwide to develop and experiment with novel nature-inspired methods. Thus, besides the
interest in evolutionary procedures that governed EAs, new
d paradigms from nature were subjected to investigation. The first
PSO models introduced the novelty of using difference vectors
among population members to sample new points in the search
space, (Souravlias and Parsopoulos, 2016), (Xue et al, 2013),
(Sugonthan, 1997). This novelty diverged from the established
procedures of EAs, which were mostly based on sampling
new points from explicit probability distributions. Additional
advantages of PSO were its potential for easy adaptation of
operators and procedures to match the specific requirements of
a given problem, as well as its inherent decentralized structure
that promoted parallelization, (Storn and Price, 1997). PSO has
gained much attention nowadays and has wide applications in
different fields such as fitness distance ratio, (Yan et al, 2013),
adaptive mutation and inertia weight, (Zhang et al, 2011) and
parameter identification in magnet synchronous motors, (Liu et
al, 2008), hybrid neural network and the level of seismic inver-
sion, (Yang et al, 2017). In this study, the parameter estimation
problem is solved by using the Particle Swarm Optimization
(PSO) method, which is the first time where this method is
used for the problem at hand. The parameter estimation will be
focused in the range of treadmill speeds from 2 up to 14 km/h
(2-14 km/h). In many studies, (Bansal et al, 2011), (Ibeas et al,
2010), the usual range of speed is (2-8 km/h), or (2-10 km/h). Therefore, the proposed methodology
is applicable in the large range of speeds from 2 to 14 km/h.
Despite this range is popular in many rehabilitation and training
exercises, it is the first time considered in this problem.

On the other hand, a Sliding Mode Controller (SMC) approach
is adopted to design the controller. The SMC has revealed
very useful in the robust control of multiple systems, such as
pneumatic cylinder as actuators for robot manipulators, (Paul
et al, 1994) and the hydraulic dynamics of the manipulator,
(Guo et al, 2008). However, this is the first time that SMC is
used to control the HR during treadmill exercise since previous
works used different control techniques such as Pontryagin, robust control
approaches or model predictive controllers, (Scalzi et al, 2012),
(Shtessel and Yuri, 2017), (GAO and Xuehui, 2016). Special
attention will be devoted to the chattering effect since this is
a crucial aspect in biomedical applications, (Lu et al, 2016).

To this end, a super-twisting based sliding mode controller will
be designed instead of a traditional SMC, (Shtessel and Yuri,
2010), (GAO and Xuehui, 2016). The super-twisting approach
will allow avoiding the undesired oscillations that a classical
sliding mode controller may cause. Simulation results will
show that our approach definitely improves the accuracy of
the model parameter estimation for these treadmill speeds, (up
to 14 km/h) and the SMC also improves the heart rate control
which has not been considered in the past.

The rest of paper is organized as follows. In section (2) we
introduce the problem formulation. In this part, we provide
the model description. In the next section, the PSO algorithm
proposed for the parameter estimation is introduced, while the
advantages of this method are commented. In addition, Section
(3) also contains the controller design procedure based on SMC.
Finally, the last section presents the simulation examples and its
comparison with alternative estimation and control methods.

2. PROBLEM FORMULATION
The following nonlinear model describes the relationship be-
tween speed and heart rate during treadmill exercise, (Esmaeili
and Ibeas, 2016), (Jang and Dae-Geun, 2016), (Su et al, 2010):

\[ x_1(t) = -a_1x_1(t) + a_2x_2(t) + a_3x_2^2(t) \quad (1) \]
\[ x_2(t) = -a_4x_2(t) + \phi(x_1(t)) \quad (2) \]
\[ \phi(x_1(t)) = \frac{a_5x_1(t)}{1 + \exp\left(-x_1(t) - a_6\right)} \quad (3) \]
\[ y(t) = x_1(t) + HR_{rest} \quad (4) \]

Where \( x(0) = [x_1(t), x_2(t)] = [0, 0] \) is the usual initial condition
and \( a_1, \ldots, a_6 \) are positive scalars that are adjusted from real
data to describe the particular response of each individual to
exercise. The output \( y(t) \) relates to the change of HR of the
person, and \( HR_{rest} \) is the value of the Heart Rate at rest. The
control input \( u(t) \) describes the speed of the treadmill. The
component \( x_1(t) \) describes the change of HR from the heart
rate at rest mainly due to the central response to exercise,
whereas the component \( x_2(t) \) describes the slower and more
complex local peripheral effects. The positive feedback signal
\( x_2 \), or a dynamic disturbance input to the \( x_1 \) subsystem, may be
treated as a reaction of HR to the effects from the peripheral
local responses or factors. In this case, the metabolites from
the peripheral local metabolism further accelerate the HR dur-
ing exercise. For instance, in the case of the peripheral local
metabolism, the accumulated metabolic by-products, such as
adenosine, K+, H+, lactic acid and other metabolites, cause
vasodilation and hyperemia inactive muscles, (Su SW et al,
2010). Vasodilation in the active muscles causes a reduction
in total peripheral resistance which in turn causes a decrease
in mean arterial blood pressure. In order to regulate the blood
pressure, the cardiac output needs to be increased, meaning that
stroke volume and HR are increased via the baroreceptor reflex,
(Zhang et al, 2011).

The nonnegative nonlinear function \( \phi(x_1) \) has the property
that \( \phi(x_1) << 1 \) when \( x_1 \) is small, whereas when \( x_1 \) is much larger
than \( a_6 \), \( \phi(x_1(t)) \) approaches the linear function \( x_1(t) \). If \( x_1 \) is
small and \( a_6 \) is large, the variable \( x_1 \) is multiplied by a small
factor(i.e. \( \frac{a_5}{1 + \exp(-(x_1(t) - a_6))} \approx 0 \) in the second equation of (1), so
\( x_2 \) becomes nearly independent of \( x_1 \). If \( x_1(0) = x_2(0) = 0 \) and
the input \( u(t) \) is small, the state \( x_1(t) \) may not be large enough
to make the factor \( \frac{a_5}{1 + \exp(-(x_1(t) - a_6))} \) significant, and \( x_2(t) \) will re-
main close to zero. As a result, system (1) can be approximated
by the system \( x_1(t) = -a_1x_1(t) + a_3x_2^2(t) \) with \( x_2(t) = 0 \).
On the other hand, if the input \( u(t) \) is sufficiently large, the state
\( x_1(t) \) will be driven to a level that the factor \( \frac{a_5}{1 + \exp(-(x_1(t) - a_6))} \) is
significant, and \( x_2(t) \) is no longer independent of \( x_1(t) \).

It is important to bear in mind that the objective of the paper is
twofold. On the one hand to propose a parameter estimation
method based on PSO, while, on the other hand, to design
a SMC controller, both things used for the first time in this
problem and also for speeds ranging from 2 to 14 km/h.
In this way, the estimation of the model’s parameters \( X = [x_1] =
[a_1, \ldots, a_6] \) is formulated as an optimization problem. Hence, the
optimization of a cost function will provide an estimation of
the parameters. The PSO algorithm will be used to solve the
so-obtained optimization problem.

3. PARAMETER ESTIMATION AND CONTROLLER
DESIGN
This section contains the description of the PSO algorithm
along with the derivation of the sliding mode controller.
3.1 Parameter estimation of the model

PSO algorithm was utilized for understanding the regulations dominating the swarms of birds and their sudden changes. PSO consists of a population (or swarm) of $M$ particles, each of which represents a $n$ dimensional potential solution of the optimization problem. In our approach, $n = 6$ is the number of parameters to be estimated. Particles are assigned random initial positions and they change their positions iteratively to reach the global optimal solution. It is desired to minimize the fitness function as the PSO iterations progress.

The parameter estimation problem is cast into an optimization one so that the minimum of the fitness cost function will provide an estimation of the parameters of the system. The Squared Error Loss (SEL) is the most common cost function to be optimized for speed estimation problems and it is also the easiest to work with from a mathematical point of view. The SEL is linked with variance and bias of an estimator, so that the cost function is formulated for the estimated parameter vector $\hat{X}_k$ at iteration step $k$ as:

$$I_k = \text{Var}(\hat{y}_k) + \text{bias}(\hat{X}_k)$$  

(5)

where $\hat{y}_k$ is the estimated output. Both terms in Eq. (2) are non-negative i.e. $(\text{Var}(\hat{y}_k) > 0, \text{bias}(\hat{X}_k) \geq 0)$, so that the minimum of the cost function $I_k$ is given by $I_k = 0$.

Therefore, when the cost function $I_k$ vanishes then $(\text{Var}(\hat{y}_k) = 0)$ and $\text{bias}(\hat{X}_k) = 0$ implying that the estimation of the parameters is performed adequately. The minimization of such cost function is done by using the PSO algorithm.

Each particle evaluates its fitness (given by Eq. (5)) and every particle $i = [1, ..., M]$ has a memory to store the value of its best own position $p_{best_i}$, which is defined as the position where the particle has minimum fitness. Besides, the best of $p_{best_i}$ of all particles, called $g_{best}$, is stored too. At each iteration $k$, the PSO modifies each dimension of the position $x_{id}$ in a particle by adding a velocity $v_{id}$ and moves the particle towards the linear combination of $p_{best_i}$ and $g_{best}$ according to:

$$v_{id}(k+1) = w v_{id}(k) + c_1 \text{rand}_1(p_{id} - x_{id}) + c_2 \text{rand}_2(p_{gd} - x_{id})$$  

(6)

$$x_{id}(k+1) = x_{id}(k) + v_{id}(k+1)$$  

(7)

In fact, according to Eqs. (6)-(7), some new particles may be out of the search space so that a projection to the boundaries of such space is included in the algorithm, (Yan et al, 2013). Moreover, the most common approach to restrict the particle position in the search space is to set the violated components of the particle equal to the value of the violated boundary. In the problem at hand, the constraint violation appears when the algorithm provides a negative value for the parameters. Consequently, the projection algorithm takes the form:

$$x_{id} = \begin{cases} 0, & x_{id} < 0 \\ x_{id}, & \text{otherwise} \end{cases}$$  

(8)

In this way, we can guarantee that the estimated parameters are non-negative and the velocity and position of each particle are updated by the equations until a termination condition is met and the algorithm finally stops. The parameters $c_1$ and $c_2$ are the so-called cognitive and social parameters, respectively, and satisfy $0 < c_1, c_2 < 1$. (Rini et al, 2014). Finally, $w$ is the inertia weight selected as $0.4 \leq w \leq 0.9$, the range where the algorithm provides the best results, (Bansal et al, 2011).

Typically, the number of subsequent iterations without improvement of the best solution and/or the dispersion of the particles current (or best) positions in the search space has been used as indicators of search stagnation. Frequently, the aforementioned termination criteria are combined in forms such as:

$$IF \ (|I_{k+1} - I_k| \leq \epsilon) \text{ OR } (k \geq k_{max}). \text{ Then Stop}$$  

(9)

where $I_k$ is the function to be optimized and $k$ stands for the iteration number, respectively, and $\epsilon$ is the corresponding user-defined tolerance. However, the search stagnation criterion can prematurely stop the algorithm even if the computational budget is not exceeded. Successful application of this criterion is based on the existence of a proper stagnation measure.

Figure 1 displays the pseudocode of the PSO algorithm developed in our study. The PSO search is carried out by the speed estimation of the model

Fig. 1. PSO pseudocode employed to solve the optimization problem.

of the particle. During the development of several generations, only the most optimistic particles can transmit information to the other ones. One of the advantages of the PSO method is that it can be applied to optimization problems of large dimensions, often producing quality solutions more rapidly than alternative methods, (Yang et al, 2017), (Eswaran et al, 2017), (Hamed et al, 2017). Also, the algorithm is terminated after a given number of iterations, or once the fitness values of the particles (or the particles themselves) are close enough in some sense.

In the results section (Section 4), we describe the M-estimator as an alternative model to compare with our estimation results,
showing that the proposed PSO method outperforms the M-estimator. Once the parameter estimation procedure has been described, the next step is to design a controller to make the heart rate track a pre-specified profile. The design of such a controller is carried out in the following section.

3.2 Super-twisting sliding mode control

The design of control strategies for nonlinear systems has attracted considerable research interest in the recent past, (Shstessel and Yuri, 2017), (Belkaid et al, 2016). Sliding mode control (SMC), as an effective robust control scheme, has been successfully applied to a wide variety of systems, (Gao and Xuehui, 2016), (Abu-Rmileh et al, 2010), (Ebrahimli et al, 2018). This section contains the design of the sliding mode control for the system (1). Thus, define the tracking error as:

\[ e = R - y \]  \hspace{1cm} (10)

where \( R \) denotes the reference signal (that is, the HR profile to be tracked) and \( y \) is the output of our system. The role of the controller is to ensure that system’s output accurately tracks the reference signal \( R \). When the system is perturbed or uncertain, the finite time stabilization is not ensured, (Vaidynathan and Sundarapandian, 2017), (Swikir et al, 2016). Hence, a reaching law based discontinuous control is developed which rejects the uncertainties of the system and ensures that the control objectives are fulfilled. The uncertainties in our system can be modelled as:

\[
\begin{align*}
\dot{x}_1(t) &= -a_1 x_1(t) + a_2 x_2(t) + a_3 \phi(t) + f_{\text{uncer}1}(x) \\
\dot{x}_2(t) &= -a_4 x_2(t) + \phi(x_1(t)) + f_{\text{uncer}2}(x) \\
\phi(x_1(t)) &= 1 + \exp \left( - (x_1(t) - a_6) \right) \\
y(t) &= x_1(t) + HR_{\text{est}}
\end{align*}
\]  \hspace{1cm} (11)

where \( f_{\text{uncer}1}(x) \) and \( f_{\text{uncer}2}(x) \) account for the unmodelled dynamics and parametric uncertainty in each of the model equations. On the other hand we need to consider the following assumptions.

Assumption 1. \( f_{\text{uncer}1}(x) \) and \( f_{\text{uncer}2}(x) \) are upper-bounded.

Assumption 2. One upper-bound for each one of these terms is known.

These are common assumptions in SMC, (Shstessel and Yuri, 2010). The sliding mode controller is composed of two parts:

\[ u = u_{\text{equiv}} - u_{\text{sliding}} \]  \hspace{1cm} (12)

where \( u_{\text{equiv}} \) is the so-called equivalent control used to remove certain terms in (11)-(12) while the sliding term \( u_{\text{sliding}} \) is the term used to counteract the uncertainties of the system and will be of the super-twisting type, (Shstessel and Yuri, 2017). This approach will also help us avoid the chattering effect, that would be very harmful in the control system. Initially, the equivalent control will be derived while the final control law will be obtained by incorporating the super-twisting sliding term according to (12).

The following sliding manifold with the integral term is proposed:

\[ S(t) = e(t) + \lambda \int_0^t e(\tau) \, d\tau \]  \hspace{1cm} (13)

where \( \lambda \) are strictly positive constant. The equivalent control is obtained by derivating (13) with respect to time and then equating the so-obtained derivative to zero. In this way we have:

\[
\begin{align*}
e(t) &= R(t) - y(t) = R(t) - x_1(t) + HR_{\text{est}} \\
\dot{e}(t) &= R(t) - \dot{x}_1(t) + HR_{\text{est}} \\
&= R(t) + a_1 x_1(t) - a_2 x_2(t) - a_3 a_6^2(t) + f_{\text{uncer}1}(t)
\end{align*}
\]  \hspace{1cm} (14)

In this way, if we substitute the above expressions into (10) and simplify we obtain. Now, the derivative of the sliding manifold reads:

\[
\begin{align*}
\dot{S}(t) &= \dot{e}(t) + \lambda e(t) \\
&= R - y + \lambda e(t) = R - x_1 + \lambda e(t) \\
&= R - (a_1 x_1 + a_2 x_2 + a_3 a_6^2 + f_{\text{uncer}1}) + \lambda e(t)
\end{align*}
\]  \hspace{1cm} (17)

If \( \dot{S}(t) = 0 \) we have:

\[
\begin{align*}
\dot{R} + a_1 x_1 - a_2 x_2 - a_3 a_6^2 - f_{\text{uncer}1} + \lambda e(t) &= 0 \\
\end{align*}
\]  \hspace{1cm} (19)

Now, if we isolate \( a_3 a_6^2 \) we obtain:

\[
\begin{align*}
a_3 a_6^2 = \dot{R}(t) + a_1 x_1 - a_2 x_2 - f_{\text{uncer}1} + \lambda e(t) \\
u^2(t) = \frac{1}{a_3} (\dot{R}(t) + a_1 x_1 - a_2 x_2) + \lambda e(t)
\end{align*}
\]  \hspace{1cm} (21)

The uncertain terms \( f_{\text{uncer}1} \) do not appear in (22) since they are unknown. Therefore, they do not appear in the equivalent control part. The super-twisting sliding term is given by, (Swikir, 2016):

\[ u_{\text{sliding}} = K|S|^\alpha \text{sgn}(S) \]  \hspace{1cm} (23)

It is important to point out that the total control command is given by (15) while being composed of the sum of (25) plus (26). Therefore, the value of both state variables \( x_1 \) and \( x_2 \) is needed to calculate the control law. The heart rate \( x_1 \) can be measured easily, as there exist multiple devices to measure the HR of an individual in real time. However, the peripheral effects \( x_2 \) cannot be measured. As a consequence, a state observer is needed in order to implement the control command in practice. The state observer is given by:

\[
\begin{align*}
\hat{x}_2(t) &= -a_4 \hat{x}_2(t) + \phi(x_1(t))
\end{align*}
\]  \hspace{1cm} (24)

With arbitrary initial condition \( \hat{x}_2(0) \), since \( x_2 \) is insufiable to obtain and \( f_{\text{uncer}1} \) is unknown. The control law reads:

\[
\begin{align*}
u(t) &= \frac{1}{a_3} (\dot{R}(t) + a_1 x_1(t) - a_2 \hat{x}_2(t) + \lambda e(t)) - K|S|^\alpha \text{sgn}(S)
\end{align*}
\]  \hspace{1cm} (25)

Despite the observer works with arbitrary initial conditions, a judicious choice is given by \( \hat{x}_2(0) = 0 \) since at the beginning for the exercise, the peripheral effects are small and the initial value of the state variable is close to zero. In this way, the initial observation error would be zero and will maintain close to zero during all the observation.

Assumption 3. The observation error at the initial time is bounded and an upper-bound for it is known.

The switching gain \( K \) has to be selected so as to guarantee the stability and reference tracking of the closed-loop system. In order to obtain a guideline for its tuning we consider the following Lyapunov function candidate:

\[ V(t) = \frac{1}{2} S^2 \]  \hspace{1cm} (26)

Its time-derivative is given by:
\(V(t) = SS = S(\dot{R} - \dot{x}_1(t) + \lambda e(t))\)
\[= S(a_2 \dot{x}_2(t) - a_3 x_1(t) - K_{a1} \text{sign}(S) - f_{uncer}(x))\]
\[= S(a_2 \dot{x}_2(t) - K_{a1} \text{sign}(S) - f_{uncer}(x))\]
\[= -K_{a3} |S|^{a_1} + S(a_2 \dot{x}_2(t) - f_{uncer}(x))\] (27)
where \(\dot{x}_2(t) = x_2(t) - x_2(t)\), represents the observation error. In order to ensure the appropriate operation of the controller, the time derivative (27) should be negative-definite, fact that is achieved if:
\[K_{a3} > a_2 |\dot{x}_2(t) - f_{uncer}(x)|\] (28)
Condition (28) can be further elaborated in the following way. The dynamics of the observation error is obtained by Eq. (27), whose result is:
\[\dot{x}_2(t) = -a_4 \dot{x}_2(t) - f_{uncer2}(x)\] (29)
The solution to this equation is given by:
\[\dot{x}_2(t) = e^{-a_4 t} \dot{x}_2(0) - \int_0^t e^{-a_4 (t-\tau)} f_{uncer2}(x) \, d\tau\] (30)
If the uncertain function \(f_{uncer2}\) is upper-bounded, i.e. \(\sup |f_{uncer2}| < \infty\), fact that holds since according to Assumption 1 the uncertainty terms are bounded, then (30) can be upper-bounded accordingly as:
\[|\dot{x}_2(t)| \leq e^{-a_4 t} |\dot{x}_2(0)| + \frac{1}{a_4} \sup |f_{uncer2}(x)| (1 - e^{-a_4 t})\] (31)
\[\leq |\dot{x}_2(0)| + \frac{1}{a_4} \sup |f_{uncer2}(x)|\] (32)
for all \(t \geq 0\). In this way, (28) is satisfied if the following condition holds:
\[K_{a3} > \left( a_2 |\dot{x}_2(0)| + \frac{a_2}{a_4} \sup |f_{uncer2}(x)| + \sup |f_{uncer1}(x)| \right)\] (33)

Thus, the switching gain \(K\) must be selected to fulfill (33), a condition that depends on an upper-bound of the observation error and upper bounds of the uncertainties. In the end, we must bear in mind that we are working with the square of the control signal so that the actual speed command is given by:
\[u_{actual} = \sqrt{\max(0, u)}\] (35)

4. SIMULATION RESULTS

This Section is composed of three subsections. First, the estimation results obtained by means of the PSO algorithm are discussed in section 4.1. Secondly, the control results obtained by using the super-twisting control law are presented in section 4.2, while the comparison between the PSO and other parameter estimation procedures and SMC comparison with PID is presented in Section 4.3.

4.1 PSO parameter estimation results

In this part, we will apply the PSO parameter estimation algorithm to the data described in tables below corresponding to ten subjects. These data are numerical data used for testing the algorithm and they do not correspond to real subjects. The parameters of the PSO algorithm are given by \(c_1 = 0.87, c_2 = 0.67, w = 58, rand_1 = 0.1, rand_2 = 0.5\) and \(\epsilon \geq 0.15\) then tolerance is small. The actual parameters of the ten subjects are given in Tables 1 and 2 and the estimated ones obtained from the PSO proposed approach are in Tables 3 and 4.

</table>

As it can be noticed from Tables 1, 2, 3 and 4, the estimated parameters obtained by the proposed PSO approach are close to the actual ones. These results mean that the PSO algorithm performs very well.

Figure 2 shows the actual heart rate corresponding to one of our subjects (subject No.3) along with the output of the estimated model obtained by using the PSO algorithm described in Section 3.1. As it can be observed in this figure, the estimated model captures the dynamics of the heart rate of each person. It means that the PSO algorithm has a good response. Moreover, PSO is able to provide accurate parameter values and able
to reproduce the behavior of the heart rate. Figure 3 displays the HR generated by the original model parametrized by the parameters in Table 1 along with the values obtained when the estimated parameters values are used to obtain the HR response according to (1)-(4). We can observe some mismatch between the actual output and the estimated one in Figure 3, which is due to the uncertain dynamics that cannot be adequately captured by the model parameters. This unmodeled dynamics will be counteracted by means of the sliding mode control.

The following figures (Fig. 4 and Fig. 5) display the evaluation of the estimated parameters for subjects No.1 and No.8 in Table 1 and the estimated one. These figures show that after a small number of iterations the estimated parameters are close to the actual ones, the fact that is displayed numerically in Tables 2, 3, and 4.

The following Figure 6 displays the actual value of parameters for the ten subjects. Despite the value of the actual parameters with exhibit a large variability, showing that the algorithm works in a variety of situations the parameters. Thus, we have Figure 7, which is the relative error of the parameters with high variability. As it can be observed, the proposed PSO algorithm is able to achieve a superb estimation since the relative error is

\[ \text{Relative Error} = \frac{\hat{a} - a_{\text{true}}}{a_{\text{true}}} \times 100 \]

which is very low and algorithm with this high variabilities has a superb response.

4.2 Control Results

In this part, we choose one person (subject No.3) to show the result. We want to highlight that similar good results are obtained for all the parameters. The controller parameters are \( \alpha = 0.5 \) and \( K = 10 \). In Fig. 8, the actual Heart rate (HR)
and the reference signal are shown. In this figure (Fig. 8), the output and the reference signal are super-impressed implying that the control objective has been achieved. The zoom of first 150 seconds in the previous figure (Fig. 8) is shown in Figure 9. On the other hand, Figure 10 shows the speed calculated from the SMC given by Eq. (10). In this case, the tracking error after the reaching phase is very small, despite the changes in the reference signal and it shows that how the SMC had a great response regards to the absence of chattering in the output and in the control command.

**4.3 Estimation and control comparisons**

Previously in some studies, researchers used different methods such as the M-estimator to solve the parameter estimation problem, (Peter and Huber, 1964). This method is effective, from the statistical point of view, to obtain an adequate estimation of the parameters. The comparison with the M-estimator procedure shows that PSO has better behavior than the previous approach, while the accuracy of the estimation parameter is increased by using PSO.

In this subsection, the theory of M-estimation is introduced for comparison purposes. The previous researchers used robust performance of estimation for two main reasons, namely: 1) there may be outliers in the data, that are sample values considered very different from the majority of the sample and 2) the data may depart from the underlying distribution assumptions, (Cheng et al, 2008), (Peter and Huber, 1964), (Maronna, 1976). This method is good for estimating the parameters, which is the reason why we compare our approach with this one. The class of M-estimators contains the maximum likelihood estimator (ML) as a special case. If we assume that the data come from the model distribution $F(m; s)$ then the log-likelihood can be written as:

$$
\sum_{i=0}^{n} \{ \log(f_0(x_i - \mu) - \log(\sigma) \}
$$

(36)

The first order condition for the M-estimator of $\mu$ is then given by:

$$
\frac{1}{n} \sum_{i=0}^{n} \psi_M(x_i - \mu) = 0
$$

(37)

while the M-estimator of scale verifies

$$
\frac{1}{n} \sum_{i=0}^{n} \rho_M(x_i - \mu) = 1
$$

(38)

with $\psi_M(u)$ being the so-called score function, and $\rho_M(u) = \psi_M(u)/u$. Under regularity conditions the ML estimators have a 100 percent efficiency, meaning that their asymptotic variance equals the inverse of the Fisher information, the lower bound of the Cramer-Rao inequality, (Tian et al,2014), (Peter and Huber, 1964). The parameters are coming from the particular...
subject (subject No.3) of Table 1, estimated by solving Eq. (17) with respect to $x_i$. The estimated parameters obtained by using the M-estimator are applied again to parametrize Eq. (1)-(4). Figure 11 demonstrates that in many points the output of PSO intersects with the reference signal and it means that PSO estimation is really close to the reference. On the other hand, the M-estimator displays an output that intercepts at some points with the reference, it has many variations in most of the points and this is not as effective as PSO. Whereas, we are calculating the fit-in error (since it is an error coming from a difference in the output of the models and actual data) in this part, that is only in open loop and it is only for estimation purposes. The fit-in error is calculated as:

$$J_{1,k} = [r_k - p_k]$$

$$J_{2,k} = [r_k - m_k]$$

where: $r_k = \text{reference}$

$p_k = \text{PSO output}$

$m_k = \text{M-estimator parameter output}$

Fig. 12 shows the fit-in results of the output in the PSO and M-estimator. We want to show that PSO outperforms the M-estimator. As it can be seen at the beginning of the process in Figure 12, PSO after 500 seconds starts definitely better than the M-estimator and it slightly goes better afterward. Both of these models have a good response, but PSO performs better during the fit-in error process. On the other hand, PSO has a lower error against the M-estimator.

Finally, in Fig. 13 the value of the cost function (Eq. (5)) in Particle Swarm Optimization and M-estimator are displayed. The cost function (2) in the PSO after 5 iterations reduces faster than the M-estimator. So the fact that can be interpreted as that estimation is performed faster in PSO method against the M-estimator, and this fact is reflected in the quality of estimation.

On the other hand, PID is a common approach in the control of systems. For this reason, it is used to solve the control problem in many studies. The SMC control will be compared with the PID controller implemented in (Girard et al, 2016). Since PID controllers are widely used in practice we will show the results achieved by the proposed controller in this scenario. In Fig.

5. CONCLUSIONS

This paper has considered the design of a sliding mode controller for the HR control during treadmill exercise. Initially, a Particle Swarm Optimization algorithm has been proposed to obtain an accurate estimation of the model parameters. Secondly, a super-twisting based sliding control law has been designed for the system in order to counteract the remaining potential unmodelled dynamics or parametric uncertainty in the system. In both situations, the range of treadmill speeds goes from 2 up to 14 km/h, range not usually employed in previous studies. Simulation results show how the proposed PSO algorithm is able to obtain accurate estimations of the model parameters while the super-twisting sliding controller is capable of obtaining zero tracking error without chattering.
